1. Introduction

The Kuwae volcano in Vanuatu (16.83°S, 168.54°E) erupted in the middle of the 15th century A.D. [Pang, 1993; Briffa et al., 1998], expelling 32–39 km3 of dense rock equivalent [Monzier et al., 1994]. This volume of expelled matter is more than six times larger that of the 1991 Pinatubo eruption and left “unmistakable marks in world climate records” [Pang, 1993]. While records of unusual weather and atmospheric optical phenomena and severe damage on agriculture [Pang, 1993], as well as the anomalously low tree ring densities [Briffa et al., 1998], point to the year 1452 as the time of the eruption, dating of the Kuwae signal derived from individual ice core record ranges from 1450 to 1464. For example, Cole-Dai et al. [1997] found an acid “spike” that lasted for four years from 1454 to 1457 in the Siple Station ice core. Palmer et al. [2002] reported deposition of a large volcanic eruption during 1459–1461 in the Law Dome record, which was also found to be the largest volcanic signal in the last seven centuries in this record. Castellano et al. [2005] assigned the Kuwae signal to the year 1460 in their EPICA Dome C core. Another Antarctic ice core, PS1 [Delmas et al., 1992], displays a prominent acid peak which they determined to be about 1450. Similarly, in the Northern Hemisphere (NH), Zielinski et al. [1994] and Zielinski [1995] found a large volcanic signal at 1460–1461 in the GISP2 record. Fisher and Koerner [1994] discovered a volcanic deposition in 1455 in the A84 ice core. Bigler et al. [2002] found a large peak lasting several years in the early 1450s in the NGT-B20 ice core. In several of these cores Kuwae is a major if not a dominant
volcanic signal. For example, the sulfate flux of the Kuwae eruption derived from Plateau Remote is five times that of the Tambora [Cole-Dai et al., 2000], which raises the question about the relative magnitude of the Kuwae and other large volcanic eruptions during the past 2000 years. Because of different site characteristics, such as the relative contribution of different air-to-snow mass transfer mechanisms (wet and dry deposition, riming, and vapor transfer) of sulfate aerosols as well as the surface elevation and irregularities, temperatures, wind speed that affect the flux of sulfate aerosols [Cole-Dai et al., 1997] and thus the magnitude of volcanic signals, studies based on multiple ice cores from both Antarctic and Greenland are required to better understand this problem, as suggested by previous studies [Robock and Free, 1995; Free and Robock, 1999; Mosley-Thompson et al., 2003].

In our study, we have incorporated the volcanic signals derived from 33 ice core records from both hemispheres to determine the timing and magnitude of the Kuwae eruption. Results obtained from these multiple ice cores reevaluate and complement the previous geological, historical and proxy data. The estimated timing of the eruption not only provides a tool to evaluate the dating of existing ice core records but serves as a volcanic reference horizon for future ice core dating and important case study for the effects of volcanic eruptions on climate change.

2. Ice Core Database and Volcanic Signal Extraction Methods

[4] After large explosive volcanic eruptions, a portion of emitted sulfate aerosols is embedded and preserved in certain glaciers and ice sheets, in the snow and ice by precipitation or by dry deposition. Thus measurement of the total acidity or the actual sulfate content in the ice cores from these areas allows relatively precise computation of a volcanic time series [Robock and Free, 1995, 1996; Robock, 2000]. While no individual ice core record is representative of past volcanism due to the large spatial variation of volcanic deposition on ice sheets [Zielinski et al., 1995, 1996; Robock, 1999], previous studies [Robock and Free, 1995; Free and Robock, 1999; Mosley-Thompson et al., 2003] suggested that results compiled from multiple ice cores can reduce the errors associated with individual records and provide a more reliable index of past volcanism. In our study, we used 33 ice cores, 13 in the NH and 20 in the Southern Hemisphere (SH). Table 1 lists the names and general information about these 33 ice cores, among which 19 ice cores, 10 in the SH and nine in the NH, contain data.
beginning in or before the 15th century. From Table 1 we also see that 24 ice cores, 17 in the SH and seven in the NH, have sulfate records. Among the 24 sulfate ice core records, only nine (7 SH, 2 NH) have records that go back to the 15th century. In this study, we used all available ice cores (i.e., the 19 records with Kuwae signals) to determine the timing of the Kuwae eruption, but only the sulfate records (i.e., the nine cores with Kuwae sulfate records) to estimate the deposition of the eruption on the Antarctic and Greenland ice sheets. The estimated deposition was evaluated and adjusted with the 24 total ice core sulfate records. The reason we choose not to use electrical conductivity measurement (ECM) records in calculating the volcanic deposition is that ECM measures acidity caused not only by sulfuric acid (H$_2$SO$_4$), but also by nitric (HNO$_3$), hydrochloric (HCl), and hydrofluoric (HF) acids, can be reduced by deposition of basic (as contrasted with acidic) aerosol particles, and depends on the temperature at the time when the measurement was taken. Figures 1 and 2 show the locations of these 33 sites, except the Mount Logan ice core which is far away from Greenland. We can see from Figures 1 and 2 that the 19 sites with Kuwae signals are relatively evenly distributed in both regions, especially for the 10 ice cores in Antarctica.

To extract the volcanic signals from the annual average time series of each ice core we used the following procedures: (1) convert the sulfate concentration time series into fluxes (see Appendix A), (2) remove the trend and the background variation with a high-pass loess filter, a locally weighted least squares quadratic estimate [Cleveland and Devlin, 1988], to remove signals longer than 31 years, (3) calculate the 31 year running median absolute deviation (MAD) of the residuals and select the potential volcanic peaks if they exceed the baseline plus 2 running MAD, (4) replace the selected peak values with the median of the original time series, (5) repeat step 2 using the time series with the peaks removed, and (6) repeat step 3 to extract the volcanic peaks. We use the loess filter and MAD because they provide robust estimates for a wide range of population distributions, and do not require a normal distribution, which is the underlying assumption for the automatic extraction method [Naveau et al., 2003] and other methods [e.g., Robock and Free, 1995, 1996] that extract peaks above a certain standard deviation limit. We chose an appropriate window length and extraction threshold by examining the properties of the detrended, peak-removed residuals such as normality, constant variance, and minimum autocorrelation. On the basis of
spectral analysis of several of the time series, the 31 year filter falls at a spectral gap, which removes long-term variations while allowing for the full strength of volcanic peaks. For volcanic events as large as the Kuwae eruption, the choice of extraction method and criteria does not affect the results. However, for small eruptions, a suitable threshold and a robust method that is resistant to the outliers are essential in extracting the signals. To be consistent with other studies that reconstruct the entire volcanic time series, we keep the same extraction procedure here even though some steps and criteria are not critical.

3. Timing of the Great Kuwae Eruption

Figure 3 shows the time series of the potential volcanic peaks extracted from the 10 SH ice core records for the period 1440–1465. On the basis of previous studies, we would expect the ice core signal of a tropical eruption to show up 1–2 years after the eruption [Cole-Dai and Mosley-Thompson, 1999; Legrand and Wagenbach, 1999]. As the Kuwae caldera is located in the SH, we would expect to see the stratospheric aerosols confined mostly to the SH and to see its signature in SH ice much more strongly than in the NH.

We can see in Figure 3 that two records (Siple Station, DML_B31) show large peaks during the period 1454–1456; and three records (Talos Dome, DML_B32 and DML_B33) have peaks during 1453–1456. All of these five cores [Cole-Dai et al., 1997; Sommer et al., 2000b; Stenni et al., 2002; Traufetter et al., 2004] were absolutely dated by counting seasonal cycles of non-sea-salt SO$_4^{2-}$, δ$^{18}$O, sodium, calcium, and/or ammonium concentrations. The dating was then evaluated and refined by looking at radionuclide and volcanic markers, usually the 1259 unknown eruption, Tambora in 1815, and Agung in 1963. However, in the Talos Dome the Kuwae eruption was set to the year AD 1452 and used as a reference horizon [Stenni et al., 2002]; in the DML_B31 and DML_B33 records the peak of Kuwae signals were fixed to the year 1455 [Sommer et al., 2000b]. Ice core records dated by multiple layer accounting are considerably more accurate, though accumulated dating errors up to 1–3 years do exist due to some ambiguous layers.

Among the rest of the ice core records, SP2001c1 [Budner and Cole-Dai, 2003] has a big signal during 1456–1458. Accounting for a possible dating error of up to ±4 years, the timing of the Kuwae deposition could lie somewhere between 1452 and 1462. The peak in Plateau Remote spans 1451–1455 in Figure 3. This core was dated using an
The age model and the Kuwae peak was fixed to 1454 and served as a reference horizon [Cole-Dai et al., 2000]. The Law Dome record [Palmer et al., 2002] was composited from three ice cores, DSS97 (1888–1995), DSS99 (1841–1888), and DSS (1301–1841), which may cause either missing or faulty annual layers at the conjunctions. Thus it is possible for the peak shown at 1460 in Figure 3 to be off by a few years. The PS1 data we have only contain volcanic signals extracted by the authors [Delmas et al., 1992], and it has a single value for each event though the authors stated that the Kuwae deposition lasted for 3 full years. The dating uncertainty is ±10 years during the period from 1259 to 1800 and the authors “redate” the Kuwae event to the year 1452 according to tree ring evidence [La Marche and Hirschboeck, 1984]. G15 [Moore et al., 1991] was dated by first using Agung, Tambora and the 1259 unknown to fix the chronology and then interpolating between these events. Therefore it is possible that the timing of Kuwae as interpreted from this core was off by several years. In general, the SH ice core records seem to suggest a 3–4 year Kuwae deposition at about 1453–1456.

Evidence from NH ice core records is less clear. As shown in Figure 4 several of the NH ice core records show double peaks during the period from 1450 to 1465, with one in the mid-1450s and the other at the beginning of 1460s. No signal was detected in the GRIPmain ice core records. Previous studies [Fisher et al., 1985; Langway et al., 1995] suggest that the Crête ice core has a high dating accuracy due to the low signal-to-noise variance ratios in terms of both accumulation rate and layer separation, plus there is virtually no melting in this site. We extracted a large acid spike during 1453–1454 in the Crête ECM record.

Figure 3. Kuwae signals extracted from the annual time series of the 10 Southern Hemisphere ice core records (see Table 1 and Figure 1). SF (in blue) is sulfate flux and ECM (in red) is electrical conductivity measurement.
counting for the ±1–2 year dating error [Hammer et al., 1980], this result suggests a Kuwae deposition during 1451–1456. Other NH ice core records that have a signal during this period are A84, Renland, and both of the NorthGRIP1 sulfate and ECM data. NGT_B20 [Bigler et al., 2002] was dated based on identification of the well-known historical volcanic layers (Katmai 1912, Tambora 1815, Laki 1783, Huaynaputina 1600, unknown 1259, and Eldgjá 934) plus annual counting using the seasonal variation of calcium and sodium. The dating accuracy is ±5 years, which places the Kuwae signal in the time interval 1446–1458. In the GISP2 record a larger signal was detected during 1458–1461. The volcanic signals in GISP2 are generally spread due to the biyearly sampling scheme used so the original signal is probably only in 1459–1460. Zielinski [1995] assigned this signal to the Kuwae eruption. Here we suggest that this 1459–1460 peak is the deposition of a local eruption at the beginning of 1460s rather than Kuwae for the following two reasons. First, we found an almost constant dating error of −1–2 years (i.e., 1 or 2 years earlier than the actual date) in GISP2 by comparing its volcanic signals with the other cores and the historical documents; therefore it is unlikely that this signal represents the deposition of Kuwae eruption found to be in the middle 1450s, based on our SH ice cores results. Second, several other NH ice cores, such as the Crête, NorthGRIP1 sulfate, A77, A84, and Dye3 deep records (Figure 4), also have separate peaks during the same period that are not due to the Kuwae aerosols. The missing of Kuwae signal in both the GISP2 and GRIPmain ice core record may be a result of

Figure 4. Kuwae signals extracted from the annual time series of the 10 Northern Hemisphere ice core records (see Table 1 and Figure 2). SF (in blue) is sulfate flux, and ECM (in red) is electrical conductivity measurement.
the natural spatial variation of volcanic deposition; or it may be caused by the loss of snow and ice during the postdepositional redistribution or even the drilling and handing processes.

[10] All of the ten SH ice core records in Figure 3 display only one dominant peak during the interval 1445–1465, suggesting that the Kuwae eruption was a single-phase volcanic event. The multiple peaks shown in some of the NH time series (Figure 4) were probably caused by signals from other sources such as local volcanic eruptions. Since the Kuwae eruption is at 17°S, it is reasonable to base our analysis on the SH ice core records and conclude that the eruption was indeed a single-phase event.

[11] In summary, the ice core records support the previous discovery that there was a large volcanic eruption somewhere during the 1450s that emitted significant amounts of sulfate aerosols into both hemispheres. Although signals derived from individual ice cores indicate different timings of the Kuwae eruption, when accounting for the dating errors associated with each record, these signal seem to point to a volcanic deposition during the period 1453–1457, suggesting that the Kuwae eruption took place in either late 1452 or early 1453. This result is consistent with previous suggestions based on the geological record [Simkin and Siebert, 1994], historical records [Pang, 1993; Simarski, 1996], and proxy data [La Marche and Hirschboeck, 1984; Pang, 1993; Briffa et al., 1998].

4. Sulfate Deposition

[12] To calculate the amount of sulfate deposited in the polar regions by the Kuwae eruption, we first adjusted the timing of the Kuwae signals in each ice core record by lining them up during 1453–1456 and fixing the highest values at year 1454. We then calculated the hemispheric average sulfate deposition based on the seven SH ice cores (SP2001c1, PS1, Plateau Remote, Talos Dome, Law Dome, Siple Station, and DML_B32) and two NH ice cores (NGT_B20 and NorthGRIP1) that have sulfate records. The resulting total sulfate deposition was 93.0 kg SO$_4$/km$^2$ and 24.8 kg SO$_4$/km$^2$ for SH and NH ice core records, respectively (Table 2). The difference between these two average values suggests an asymmetric distribution of the volcanic debris.

[13] To evaluate how representative these seven SH and two NH ice core records are, we compared the average sulfate depositions derived from these records to those from a larger number of ice cores for several other well-known volcanic events when more ice core records were available. In the SH we calculated sulfate deposition averaged from the seven cores and those from 17 records for the 1809 unknown, 1815 Tambora, and 1883 Krakatau eruptions. These results, together with those for the NH ice core comparisons, are shown in Table 2. We also plotted in Figure 5 the sulfate fluxes averaged over the seven versus 17 SH ice cores and those from 17 records for the 1809 unknown, 1815 Tambora, and 1883 Krakatau eruptions. Our results show that the sulfate fluxes based on these seven SH ice cores records are very close, within 5%, to those from 17 SH records for the five events chosen. Therefore it is reasonable to assume that our estimation of sulfate fluxes for the Kuwae eruption based on the seven SH cores is representative of what we would obtain from the 17 SH ice core records.

[14] Similarly, we calculated the average sulfate deposition of the two Greenland cores and the total seven cores for the Laki, 1809 unknown, 1815 Tambora, and 1883 Krakatau eruptions (Table 2). The results based on the two northern Greenland ice core records are smaller than those averaged over the seven Greenland cores. Also listed in Table 2 are the average sulfate depositions for the unknown, Tambora, and Krakatau eruptions from six Program for Arctic Regional Climate Assessment (PARCA) [Mosley-Thompson et al., 2003] ice cores, and 12 Greenland cores from Clausen and Hammer [1988]. We can see that for all of the three events, the average sulfate deposition of these two other groups of Greenland ice core records is about twice as large as those of the two NH records. Previous studies [e.g., Zielinski et al., 1997] found that there are large spatial variations in the volcanic depositions among different NH ice cores. We also found, for instance, that the Tambora deposition ranges from 25 kg/km$^2$ in B20 (79°N) to 73 kg/km$^2$ in GISP2 (72.6°N) and 85 kg/km$^2$ in 20D (65°N). Since both NGT_B20 and NorthGRIP1 (75.1°N)

*All values are calculated in the same way. The 7 Southern Hemisphere (SH) cores: SP2001, PS1, Plateau Remote, Talos Dome, Law Dome, Siple Station, and B32. The 17 SH cores: the above seven cores plus SP95, ITASE015, ITASE005, ITASE004, ITASE013, TASE001, ITASE991, Dyer, Dome C, and PS14. The 2 Northern Hemisphere (NH) cores: B20 and NorthGRIP1. The 7 NH cores: the above two cores plus Greenland Site A and T, GISP2, 20D, Mount Logan. See Table 1 for details on these cores. PARCA data from four cores (GEIS, D2, D3, and Raven) for unknown and Tambora and five cores (D2, D3, Raven, Humboldt, and NASA-U) for Laki are from Table 2 of Mosley-Thompson et al. [2003]. CH1988 data obtained by averaging the sulfate depositions of 12 and 11 NH cores from Table 4 of Clausen and Hammer [1988]. Deposition values are in kg/km$^2$.

These are estimated values by multiplying the Kuwae deposition in columns 4 and 6 with the average ratios of 7 versus 17 SH and 2 versus 7 NH ice core mean depositions, respectively. Thus these two values roughly represent the average Kuwae depositions if all of the 17 SH and 7 NH ice cores were available. The Krakatau signal does not show in the Mount Logan ice core record. Therefore the total deposition for the Krakatau eruption is averaged over six NH ice core records instead of seven.

---

The table above provides the average total sulfate depositions and the corresponding standard deviations based on different groups of ice cores for the Laki, 1809 Unknown, Tambora, and Krakatau Eruptions. The depositions are calculated for both the Southern Hemisphere (SH) and Northern Hemisphere (NH) ice cores. The SH core records are more consistent, with average sulfate depositions of 93.0 kg SO$_4$/km$^2$ for the seven SH ice cores and 24.8 kg SO$_4$/km$^2$ for the 17 SH ice cores. The NH core records show more variability, with an average sulfate deposition of 25.9 kg SO$_4$/km$^2$ for the two NH ice cores. The table also includes data from additional programs, such as the Program for Arctic Regional Climate Assessment (PARCA), for comparison.
are located in northern Greenland with very low accumulation rates (10 and 15 cm water equivalent per year, respectively) we speculate that this is the major reason why the average deposition from these two records is smaller than that derived from the seven records in our study and the two other groups of Greenland records. To make the estimation of Kuwae deposition representative of the entire Greenland, we first calculated the ratio of average deposition from the total seven NH cores to those from these two cores for the four later eruptions and obtained the average ratio of 1.8, which is close to the ratio obtained from the two other groups of Greenland records as mentioned above. Then, we adjust the estimation of Kuwae deposition by multiplying the Kuwae deposition obtained from the 2 NH ice cores by a factor of 1.8 and obtained a deposition of 44.6 kg SO$_4$/$\text{km}^2$.

The adjusted result is listed in Table 2 and also plotted in Figure 5. If we apply the same procedure to the SH, we obtain the adjusted estimation of Kuwae deposition in the Antarctic of 97.7 kg SO$_4$/$\text{km}^2$, which is very close to our original estimation.

Comparing the sulfate deposition of Kuwae eruption to that for the Tambora eruption (Figure 5 and Table 2) we find that the magnitude of the Kuwae deposition is smaller than that for Tambora for the NH, but much larger for the SH. The greater hemispheric asymmetry of Kuwae as compared to Tambora is reasonable given that Kuwae (17°S) is much farther from the Equator than Tambora (8°S). On the other hand, besides the location of an eruption, the distribution of volcanic debris also depends heavily on the time of the year when the eruption took place, the location of the Intertropical Convergence Zone, the Quasi-Biennial Oscillation, and the stratospheric winds on the day of the eruption. These factors introduce an uncertainty when trying to estimate hemispheric loading from an eruption, but if we know the deposition, we can infer stratospheric loading for each hemisphere. This is illustrated by the 1963 Agung eruption, which occurred at 8°S, the same latitude as Tambora, but also dispersed two thirds of its volcanic aerosols into the SH, the same proportion as Kuwae, but different to that of Tambora’s aerosols which were more evenly distributed.

Table 2 also shows the standard deviations of volcanic sulfate deposition for each eruption, from which we can see that there are large spatial variations in both Antarctic and Greenland ice cores. Several factors can account for this variation, such as surface irregularity, elevation, temperature, wind redistribution, and relative contribution of wet-dry deposition. Figure 6 shows the ratios between the net deposition of Kuwae and Tambora sulfate aerosols. The use of these ratios eliminates much of the intersite variability described above [Cole-Dai et al., 1997]. However, Plateau Remote still has an unusually large ratio (5.6) followed by Talos Dome (3.8), compared with the average ratio (1.1) of the other six ice cores. Cole-Dai et al. [2000] suggested that
the high value in Plateau Remote was caused by the partial loss or gain of snow within annual layers, whose effects are more pronounced in the low-accumulation sites; whereas Castellano et al. [2005] speculated that the Kuwae distribution pattern can be a real spatial variation in its depositional fluxes. The high ratios in these two sites doubled the overall average ratio between Kuwae and Tambora, and our results may overestimate the mean Kuwae sulfate deposition in Antarctica if the high ratios in the above two sites are actually caused by net gain of snow. This once again addresses the importance of using multiple (as many as available) ice cores with full spatial coverage to obtain the forcing index of past volcanism.

5. Conclusions

[17] We have used 33 ice core records, 13 from the Northern Hemisphere and 20 from the Southern Hemisphere, to examine the timing and magnitude of the great Kuwae eruption in the mid-15th century. Our results suggest that the Kuwae eruption is a single-phase eruption which took place in late 1452 or early 1453, producing significant depositions that lasted up to four years in both Greenland and Antarctic ice sheets. The Kuwae signals detected in ice cores from both polar regions confirm the potential of this eruption for global climatic impacts. The large difference between the two hemispheric-average sulfate deposition densities (97.7 kg/km$^2$ in the SH versus 44.6 kg/km$^2$ in the NH) indicates an asymmetric distribution of the volcanic debris between the two hemispheres. Our results also suggest that the Kuwae eruption caused one of the largest aerosol events in the past 700 years, probably surpassing the magnitude of the aerosol cloud caused by Tambora eruption in 1815.

[18] Witter and Self [2006] calculated the total atmospheric sulfate aerosol loading from the Kuwae eruption and found it to lie somewhere between 235 and 414 Tg. They used geological techniques to estimate the amount of sulfur the eruption actually injected into the stratosphere. By measuring the amount of sulfate that was deposited in ice cores, in theory one could do an inverse calculation to estimate the stratospheric loading, and then use this information to calculate the radiative forcing of the climate system [e.g., Stenchikov et al., 1998], one of the ultimate goals of our research. However, to do this inverse calculation, one would have to explicitly model the stratospheric, cross-tropopause, and then tropospheric transport; microphysical, precipitation, and deposition mechanisms; as well as effects of sastrugi on

Figure 6. Spatial distribution of the ratio between the net deposition for Kuwae and Tambora eruption in eight Antarctic ice cores.
the ice; no one has done such a calculation yet. That work is currently underway and will be reported in a subsequent paper.

Appendix A

19 Procedure to calculate sulfate fluxes for ice cores with sulfate concentration records.

A1. Cores With Sulfate Contents in μeq/L

1. Assume the density of the sample solution is similar to that of water, i.e., 1 μeq SO₄/L = 1 μeq SO₄/kg.
2. Use 1 kg/L as the density if the accumulation is in water equivalent, and 0.85 kg/L as the density if the accumulation is in ice equivalent.
3. Multiply the sulfate content (in μeq/kg) with the factor \[ L = 48 \text{ (g/eq SO}_4^2^- \text{)} \times \text{annual accumulation (m/yr)} \] in either water or ice equivalents) × water or ice density (in kg/L) or \[ L = 48 \text{ (g/eq SO}_4^2^- \text{)} \times \text{annual accumulation (cm}^2 \text{m}^-2 \text{yr}^-1 \text{)} \text{or (kg/km}^2 \text{yr}} \] to convert them to fluxes (kg/km² yr).

A2. NorthGRIP1

Since the NorthGRIP1 record we used only contains the sulfate content (in μeq/kg) corresponding to annual depth intervals and the 55 cm average ice or snow density for the first 100 m of ice core, we used the following procedure to calculate the sulfate fluxes:

1. Linearly interpolate the 55 cm averaged densities for the first 100 m of ice core to the depth intervals that correspond to the annual depositions.
2. Assume the ice density as 0.85 kg/L for the data after the first 100 m.
3. Multiply the sulfate content (in μeq/kg) with the factor \[ L = 48 \text{ (g/eq SO}_4^2^- \text{)} \times \text{annual deposition (in m) × ice density for each annual depth interval (in kg/L)} \] to convert them to fluxes (kg/km² yr).

A3. Cores With Sulfate Contents in μg/L, ng/g, or ppb

1. Assume the density of the sample solution is the same as that of water, i.e., 1 μg/L ≈ 1 μg/kg = 1 ng/g = 1 ppb.
2. Use 1 kg/L as the density if the accumulation is in water equivalent, and 0.85 kg/L as the density if the accumulation is in ice equivalent.
3. Multiply the sulfate content with the factor \[ L = \text{annual accumulation (m/yr in either water or ice equivalents)} × \text{water or ice density (kg/L)} \] or just with the annual accumulation if it is in \( \text{(g cm}^2 \text{m}^-2 \text{yr}^-1 \text{)} \text{or (kg/km}^2 \text{yr}} \) to convert them to fluxes (kg/km² yr).

Acknowledgments. We thank all the scientists who have supplied us with ice core records both for the difficult work of obtaining and analyzing the cores and for allowing us to use them. We thank Philippe Naveau for valuable discussions on signal extraction methods. This work is supported by NOAA grant NA03-OAR-4310155 and the Chaire du Développement Durable de l’École Polytechnique, Paris, France.
